# Dynamic Random Testing of Web Services: A Methodology and Evaluation

Chang-Ai Sun<sup>®</sup>, Senior Member, IEEE, Hepeng Dai, Guan Wang, Dave Towey<sup>®</sup>, Member, IEEE, Tsong Yueh Chen<sup>®</sup>, Member, IEEE, and Kai-Yuan Cai

Abstract—In recent years, service oriented architecture (SOA) has been increasingly adopted to develop distributed applications in the context of the Internet. To develop reliable SOA-based applications, an important issue is how to ensure the quality of web services. In this article, we propose a dynamic random testing (DRT) technique for web services, which is an improvement over the widely-practiced random testing (RT) and partition testing (PT) approaches. We examine key issues when adapting DRT to the context of SOA, including a framework, guidelines for parameter settings, and a prototype for such an adaptation. Empirical studies are reported where DRT is used to test three real-life web services, and mutation analysis is employed to measure the effectiveness. Our experimental results show that, compared with the three baseline techniques, RT, Adaptive Testing (AT) and Random Partition Testing (RPT), DRT demonstrates higher fault-detection effectiveness with a lower test case selection overhead. Furthermore, the theoretical guidelines of parameter setting for DRT are confirmed to be effective. The proposed DRT and the prototype provide an effective and efficient approach for testing web services.

Service oriented architecture (SOA) [1] defines a loosely coupled, standards-based, service-oriented application development paradigm in the context of the Internet. Within SOA, three key roles are defined: service providers (who develop and own services); service requestors (who consume or invoke services); and a service registry (that registers services from providers and returns services to requestors). Applications are built upon services that present functionalities through publishing their interfaces in appropriate repositories, abstracting away from the underlying implementation. Published interfaces may be searched by other services or users, and then invoked. Web services are the realization of SOA based on open standards and infrastructures [2]. Ensuring the reliability of SOA-based applications can become critical when such applications implement important business processes.

Software testing is a practical method for ensuring the quality and reliability of software. However, some SOA features can pose challenges for the testing of web services [3],

[4]. For instance, service requestors often do not have access 35 to the source code of web services which are published and 36 owned by another organization, and, consequently, it is not 37 possible to use white-box testing techniques. Testers may, 38 therefore, naturally turn to black-box testing techniques. 39

Random Testing (RT) [5] is one of the most widely- 40 practiced black-box testing techniques. Because test cases in 41 RT are randomly selected from the input domain (which 42 refers to the set of all possible inputs of the software under 43 test), it can be easy to implement. Nevertheless, because RT 44 does not make use of any information about the software 45 under test (SUT), or the test history, it may be inefficient in 46 some situations. In recent years, many efforts have been made 47 to improve RT in different ways [6], [7], [8]. Adaptive random 48 testing (ART) [7], [9], for example, has been proposed to 49 improve RT by attempting to have a more diverse distribution 50 of test cases in the input domain.

In contrast to RT, partition testing (PT) attempts to generate 52 test cases in a more "systematic" way, aiming, to use fewer test 53 cases to reveal more faults. When conducting PT, the input 54 domain of the SUT is divided into disjoint partitions, with test 55 cases then selected from each and every one. Each partition is 56 expected to have a certain degree of homogeneity—test cases 57 in the same partition should have similar software execution 58 behavior. Ideally, a partition should also be homogeneous in 59 fault detection: If one input can reveal a fault, then all other 60 inputs in the same partition should also be able to reveal 61 a fault.

RT and PT are based on different intuitions, and each 63 have their own advantages and disadvantages. Because it is 64 likely that they can be complementary to each other, detecting different faults, it is intuitively appealing to investigate 66 their integration in random partition testing (RPT).

In traditional RPT [6], the partitions and corresponding test profiles remain constant throughout testing, which may not be the best strategy. Independent researchers have observed that fault-revealing inputs tend to cluster into "continuous regions" [10], [11]—there is similarity in the execution behavior of neighboring software inputs. Based on software cybernetics, Cai *et al.* proposed adaptive testing (AT) to control the testing process [12], however, AT's decision-making incurs an extra computational overhead. To alleviate this, dynamic random testing (DRT) [6] was proposed by Cai *et al.*, aiming to improve on both RT and RPT.

In practice, web services have usually been tested by the service providers, and simple or easy-to-test faults have been removed, meaning that the remaining faults are normally hard to detect. For ensuring a higher reliability of the web services, a simple RT strategy may not be appropriate [13], especially when the scale is large, or there are some stubborn faults.

In this paper, we present a DRT approach for web services, as an enhanced version of RT adapted to the context of SOA. We examine key issues of such an adaptation, and, accordingly, propose a framework for testing web services that combines the principles of DRT [6] and the features of web services. To validate the fault detection effectiveness and efficiency of the proposed DRT method in the context of SOA, we conduct a comprehensive empirical study. We also explore the impact factors of the proposed DRT, and provide guidelines for setting DRT parameters based on a theoretical analysis. Finally, we compare the performance of the proposed DRT with other baseline techniques.

This paper extends our previous work [14] in the following aspects. First, this paper extensively examines the challenges and practical situations related to testing web services (Section 2.2). It also extensively discusses the limitations of RT, PT, RPT, and AT, when they are used for testing web services (Section 1). Second, although previous work [14] provided a coarse-grained framework for DRT of web services, PT was not studied. In contrast, this paper provides a comprehensive solution based on partitioning (Section 4.4.1). Third, based on a theoretical analysis (Section 3.2), this paper provides guidelines for setting DRT parameters. Such guidelines are crucial to enhance the practical application of DRT, which was not covered in previous work [14]. Fourth, previous work [14] only evaluated the fault detection effectiveness and efficiency of the proposed approach (DRT) in terms of the F-measure and T-measure, and only two small web services (ATM Service and Warehouse Service) were used in the evaluation of its performance. This paper, in contrast, provides a comprehensive evaluation that not only evaluates the fault detection effectiveness of the proposed approach in terms of the Fmeasure, F2-measure, and T-measure (Section 5.1), but also evaluates its efficiency in terms of F-time, F2-time, and T-time (Section 5.3). Furthermore, we also examine three real-life web services, comparing the fault-detection effectiveness and efficiency of the proposed approach with those of RT, RPT, and AT. Statistical analysis is used to validate the significance of the empirical evaluations and comparisons (Sections 5.1 and 5.3), which was not covered in previous work [14]. Extending again the previous work [14], we also examine the relationship between the number of partitions and the optimal control parameter settings for DRT, evaluating the usefulness of guidelines provided by the theoretical analysis (Section 5.2).

The contributions of this work, combined with previous work 129 [14], include:

- We develop an effective and efficient testing method 131 for web services. This includes a DRT framework that 132 addresses key issues for testing web services, and a 133 prototype that partly automates the framework.
- We evaluate the performance of DRT through a series 135 of empirical studies on three real web services. These 136 studies show that DRT has significantly higher fault-137 detection efficiency than RT and RPT. That is, to detect 138 a given number of faults, DRT uses less time and fewer 139 test cases than RT and RPT.
- We provide guidelines for the DRT parameter set- 141 tings, supported by theoretical analysis, and vali- 142 dated by the empirical studies.

The rest of this paper is organized as follows. Section 2 144 introduces the underlying concepts for DRT, and web serv- 145 ices. Section 3 presents the DRT framework for web services, 146 guidelines for its parameter settings, and a prototype that partially automates DRT. Section 4 describes an empirical study 148 where the proposed DRT is used to test three real-life web 149 services, the results of which are summarized in Section 5. 150 Section 6 discusses related work and Section 7 concludes the 151 paper.

#### 2 BACKGROUND

In this section, we present some of the underlying concepts 154 for DRT, and web services. 155

## 2.1 Dynamic Random Testing (DRT)

DRT combines RT and PT, with the goal of benefitting from 157 the advantages of both. Given a test suite TS classified into 158 m partitions (denoted  $s_1, s_2, \ldots, s_m$ ), suppose that a test case 159 from  $s_i$  ( $i = 1, 2, \ldots, m$ ) is selected and executed. If this test 160 case reveals a fault,  $\forall j = 1, 2, \ldots, m$  and  $j \neq i$ , we then set 161

$$p_{j}' = \begin{cases} p_{j} - \frac{\varepsilon}{m-1} & \text{if } p_{j} \ge \frac{\varepsilon}{m-1} \\ 0 & \text{if } p_{j} < \frac{\varepsilon}{m-1} \end{cases}, \tag{1}$$

where  $\varepsilon$  is a probability adjusting factor, and then

$$p_i' = 1 - \sum_{j=1, j \neq i}^{m} p_j'.$$
 (2)

164

169

Alternatively, if the test case does not reveal a fault, we set

$$p_i' = \begin{cases} p_i - \varepsilon & \text{if } p_i \ge \varepsilon \\ 0 & \text{if } p_i < \varepsilon \end{cases}, \tag{3}$$

and then for  $\forall j = 1, 2, \dots, m$  and  $j \neq i$ , we set

$$p'_{j} = \begin{cases} p_{j} + \frac{\varepsilon}{m-1} & \text{if } p_{i} \ge \varepsilon \\ p_{j} + \frac{p'_{i}}{m-1} & \text{if } p_{i} < \varepsilon \end{cases}$$
 (4)

Algorithm 1 describes DRT. In DRT, the first test case is 174 taken from a partition that has been randomly selected 175 according to the initial probability profile  $\{p_1, p_2, \dots, p_m\}$  176

(Lines 2 and 3 in Algorithm 1). After each test case execution, the test profile  $\{\langle s_1, p_1 \rangle, \langle s_2, p_2 \rangle, \dots, \langle s_m, p_m \rangle\}$  is updated by changing the values of  $p_i$ : If a fault is revealed, Formulas (1) and (2) are used; otherwise, Formulas (3) and (4) are used. The updated test profile is then used to guide the random selection of the next test case (Line 8). This process is repeated until a termination condition is satisfied (Line 1). Examples of possible termination conditions include: "testing resources have been exhausted"; "a certain number of test cases have been executed"; and "a certain number of faults have been detected".

# Algorithm 1. DRT

**Input:**  $\varepsilon, p_1, p_2, \ldots, p_m$ 

- 1: while termination condition is not satisfied
- 2: Select a partition  $s_i$  according to the testing profile  $\{\langle s_1, p_1 \rangle, \langle s_2, p_2 \rangle, \dots, \langle s_m, p_m \rangle\}$ .
- 3: Select a test case t from  $s_i$ .
- 4: Test the software using t.
- 5: **if** a fault is revealed by *t* **then**
- 6: Update  $p_j$  (j = 1, 2, ..., m and  $j \neq i$ ) and  $p_i$  according to Formulas 1 and 2.
- 7: **else**
- 8: Update  $p_j$  (j = 1, 2, ..., m and  $j \neq i$ ) and  $p_i$  according to Formulas 3 and 4.
- 9: end if
- 10: end while

As can be seen from Formulas (1) to (4), updating the test profile involves m simple calculations, thus requiring a constant time. Furthermore, the selection of partition  $s_i$ , and subsequent selection and execution of the test case, all involve a constant time. The execution time for one iteration of DRT is thus a constant, and therefore the overall time complexity for DRT to select n test cases is  $O(m \cdot n)$ .

## 2.2 Web Services

A web service is a platform-independent, loosely coupled, self-contained, programmable, web-enabled application that can be described, published, discovered, coordinated and configured using XML artifacts for the purpose of developing distributed interoperable applications [1]. A web service consists of a description (usually specified in WSDL) and implementation (written in any programming language). Web services present their functionalities through published interfaces, and are usually deployed in a service container. Invocation of a web service requires analysis of the input message in its WSDL, test data generation based on its input parameters, and wrapping of test data in a SOAP message.

A web service is a basic component of SOA software, and, accordingly, the reliability of such SOA software depends heavily on the quality of the component web services. While testing is an obvious potential activity to help assuring the quality of web services, due to the unique features of SOA, web service testing can be more challenging than traditional software testing [4]. Some of these features include:

 Lack of access to service implementation: Normally, web service owners will not make the source code of their web services accessible. Typically, service users only have access to the service interface defined in a WSDL

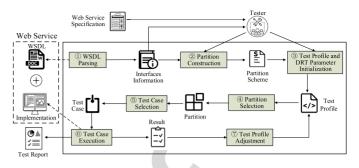

Fig. 1. DRT for web services framework.

file, which means that white-box testing approaches 234 are not possible. 235

- Incomplete documentation or specification: A service pro- 236 vider may only offer an incomplete or inaccurate 237 description of a service's functional and non-functional 238 behavior. This makes it difficult to decide whether or 239 not a test passes, especially when details about behavior or restrictions on implementations are missing [15]. 241
- Lack of control: Unlike traditional software testing 242
   where testers can control the execution of the software 243
   under test, there is usually no opportunity to intervene 244
   in the execution of the web service under test, which is 245
   often deployed in a remote service container. 246
- Side effects caused by testing: A large number of tests 247 may introduce an additional communication load, 248 and hence impact on the performance of the web ser- 249 vice under test. This suggests that the number of 250 tests should be kept as low as possible [16].

#### 3 DRT FOR WEB SERVICES

In this section, we describe a framework for applying DRT 253 to web services, discuss guidelines for setting DRT's param-254 eters, and present a prototype that partially automates DRT 255 for web services.

#### 3.1 Framework

Considering the principles of DRT and the features of web 258 services, we propose a DRT for web services framework, as 259 illustrated in Fig. 1. In the figure, the DRT components are 260 inside the box, and the web services under test and testers 261 are located outside. Interactions between DRT components, 262 the web services, and testers are depicted in the framework. 263 We next discuss the individual framework components.

- 1) WSDL Parsing. Web services are composed of serv- 265 ices and the relevant WSDL documents. By parsing 266 the WSDL document, we can get the input informa- 267 tion for each operation in the services. This includes 268 the number of parameters, their names and types, 269 and any additional requirements that they may have. 270
- 2) Partition Construction. Partition testing (PT) refers to a 271 class of testing techniques that classify the input 272 domain into a number of partitions [17]. Because DRT 273 is a black-box testing technique, combining RT and PT, 274 the PT approaches used are at the specification level. 275 Various approaches and principles for achieving convenient and effective partitions have been discussed in 277

the literature [17], [18]. The input domain of the web service under test (WSUT) can be partitioned based on the WSUT specifications and the parsed parameters. Once partitioned, testers can assign probability distributions to the partitions as an initial testing profile. This initial testing profile can be assigned in different ways, including using a uniform probability distribution, or one that sets probabilities according to the importance of the partition: For example, a partition within which faults were previously detected should be given higher priority.

- Test Profile and DRT Parameter Initialization. Testers need to initialize the test profile, a simple way of doing which would be the use of a uniform probability distribution  $(p_1 = p_2 = \ldots = p_k = 1/k)$ , where k denotes the number of partitions, and  $p_i$  (i = 1, 2, ..., k) denotes the probability of selecting the *i*th partition). They also need to set the DRT parameters (guidelines for which are introduced in Section 3.2).
- Partition Selection. DRT randomly selects a partition  $s_i$  according to the test profile.
- Test Case Selection. DRT selects a test case from the selected partition  $s_i$  according to a uniform distribution.
- Test Case Execution. The relevant DRT component receives the generated test case, converts it into an input message, invokes the web service(s) through the SOAP protocol, and intercepts the test results (from the output message).
- Test Profile Adjustment. Upon completion of each test, its pass or fail status is determined by comparing the actual and expected results (a pass status if both are the same). The pass or fail status is then used to adjust the (partition) probability distribution accordingly. Situations where determination of the test outcome status is not possible (i.e., in the presence of the oracle problem [19], [20]) may potentially be addressed using metamorphic testing [21].

Generally speaking, DRT test case generation is influenced by both the probability distribution (for selection of the relevant partition), and the principles of RT—combining the effectiveness of PT with the ease of RT. Because our technique is based on PT, it is necessary that the partition details be provided (by the tester), which can easily be done through analysis of the input parameters and their constraints, as described in the specification of the web service under test. Once the partition details are available, then it is not difficult to set an initial test profile. The tester can, for example, simply use a uniform probability distribution ( $p_1 = p_2 = ... = p_m = 1/m$ , where m denotes the number of partitions, and  $p_i$  (i = 1, 2, ..., m)denotes the probability of selecting the *i*th partition). In Section 3.2, we provide some guidelines for how to set the DRT parameters. Furthermore, many of the components in the DRT for web services framework can be automated. To make it easier for potential adopters of DRT for web services, we have also developed a prototype application (described in Section 3.3).

#### 3.2 Guidelines for Parameter Setting

Our previous work [14] found that the DRT performance depends on the number of partitions and the parameter  $\varepsilon$ .

We next explore these impacts through a theoretical analysis, which, to be mathematically tractable, has the following 338

- The failure rate  $\theta_i$  of each partition  $s_i$  (i = 1, 2, ..., m, 340 and m > 1) is unknown, but can be estimated.
- Each failure rate  $\theta_i$  (i = 1, 2, ..., m, and m > 1) 342 remains unchanged throughout the testing process (faults are not removed after their detection).
- Test cases are selected with replacement, which means 345 that some test cases may be selected more than once.

A principle of the DRT strategy is to increase the selection 347 probabilities (by amount  $\varepsilon$ ) of partitions with larger failure rates. In addition to the impact of the parameter  $\varepsilon$ , the number 349 of partitions also influences the speed of updating the test profile (Formulas (1) to (4)). Therefore, for a given number of par- 351 titions, we are interested in investigating what values of  $\varepsilon$  352 yield the best DRT performance.

Letting  $\theta_M$  denote the maximum failure rate, and  $s_M$  354 denote partitions with that failure rate, then  $p_i^n$  denotes the 355 probability of executing the nth test case from partition  $s_i$ . 356 As testing proceeds, the probability  $p_M$  of partition  $s_M$  being 357 selected is expected to increase:

$$p_M^{n+1} > p_M^n. (5) _{360}$$

In order to achieve the best performance, the probability 362 of selecting the partition  $s_M$  (which has the maximum fail-  $_{363}$ ure rate) is expected to increase. To achieve this, the increase 364 in probability of  $s_M$  being selected for the next round should 365 be larger than that for other partitions. We further analyze 366 sufficient conditions for this goal, and can accordingly 367 derive an interval for  $\varepsilon$ .

Initially, the test profile is  $\{\langle s_1, p_1^0 \rangle, \langle s_2, p_2^0 \rangle, \dots, \langle s_m, p_m^0 \rangle\}$ , which, after n test cases have been executed, is then updated 370to  $\{\langle s_1, p_1^n \rangle, \langle s_2, p_2^n \rangle, \dots, \langle s_m, p_m^n \rangle\}$ . During the testing process, 371  $p_i^n$  is increased or decreased by the value  $\varepsilon$ , which is relatively 372 small (set to 0.05 in previous studies [22], [23]). Because the 373 initial  $p_i^0$  is larger than  $\varepsilon$ , and the adjustment of  $p_i$  is relatively small (Formulas (1) to (4)), the following two situations are 375 rare, and thus not considered here:  $p_i < \varepsilon/(m-1)$  or  $p_i < \varepsilon$  376  $(i = 1, 2, \ldots, m).$ 

To explore the relationship between  $p_i^{n+1}$  and  $p_i^n$ , we calculate the conditional probability,  $p(i|\delta)$ , of the following 379 four situations (denoted as  $\delta_1, \delta_2, \delta_3$ , and  $\delta_4$ ):

Situation 1 ( $\delta_1$ ):

If  $t_n \notin s_i$  and a fault is detected by  $t_n$ , then  $p(i|\delta_1)$  is calculated according to Formula (1):

$$p(i|\delta_1) = \sum_{i \neq j} \theta_j \left( p_i^n - \frac{\varepsilon}{m-1} \right).$$

If  $t_n \in s_i$  and a fault is detected by  $t_n$ , then  $p(i|\delta_2)$  is calculated according to Formula (2):

$$p(i|\delta_2) = \theta_i(p_i^n + \varepsilon).$$

If  $t_n \in s_i$  and no fault is detected by  $t_n$ , then  $p(i|\delta_3)$  is 392 calculated according to Formula (3):

$$p(i|\delta_3) = (1 - \theta_i)(p_i^n - \varepsilon).$$
395
396

380

381

385

387

390

4) If  $t_n \notin s_i$  and no fault is detected by  $t_n$ , then  $p(i|\delta_4)$  is calculated according to Formula (4):

$$p(i|\delta_4) = \sum_{i \neq j} (1 - \theta_j) \left( p_i^n + \frac{\varepsilon}{m-1} \right).$$

Therefore,  $p_i^{n+1}$  for all cases together is:

$$p_i^{n+1} = p_i^n + Y_i^n, (6)$$

where

$$Y_i^n = \frac{\varepsilon}{m-1} (2p_i^n \theta_i m - p_i^n m - 2p_i^n \theta_i + 1) - \frac{2\varepsilon}{m-1} \sum_{j \neq i} p_j^n \theta_j.$$

$$(7)$$

From Formula (7), we have:

$$Y_{M}^{n} - Y_{i}^{n} = \frac{2\varepsilon}{m-1} \left( m(p_{M}^{n}\theta_{M} - p_{i}^{n}\theta_{i}) - \frac{m(p_{M}^{n} - p_{i}^{n})}{2} \right).$$
(8)

Before presenting the final guidelines, we need the following lemma.

**Lemma 1.** If 
$$p_i^n - p_M^n > 2(p_i^n \theta_i - p_M^n \theta_M)$$
, then  $p_M^{n+1} > p_M^n$ .

**Proof.** See Appendix A, which can be found on the Computer Society Digital Library at http://doi.ieeecomputersociety.org/TSC.2019.2960496.

Accordingly, we can now present the following theorem that states a sufficient condition for achieving  $p_M^{n+1}>p_M^n$ .

**Theorem 1.** For failure rate  $\theta_{min} = min\{\theta_1, \dots, \theta_m\}$ ,  $\theta_M > \theta_{min}$ , if  $0 < \theta_{min} < \frac{1}{2}$ , the following condition is sufficient to guarantee that  $p_M^{n+1} > p_M^n$ :

$$\frac{2m\theta_{min}^2}{1 - 2\theta_{min}} < \varepsilon < \frac{(m-1)m\theta_{min}}{2(m+1)}.$$
 (9)

**Proof.** See Appendix A, available in the online supplemental material.

In summary, when  $\frac{1}{2} < \theta_M < 1$ , there is always an interval  $\mathcal{I}$ :

$$\varepsilon \in \left(\frac{2m\theta_{min}^2}{1 - 2\theta_{min}}, \frac{(m-1)m\theta_{min}}{2(m+1)}\right) \tag{10}$$

where  $\theta_{min} \leq \theta_i, i \in \{1, 2, ..., m\}$ , and  $\theta_i \neq 0$ , which can guarantee  $p_M^{n+1} > p_M^n$ .

From the proof in Appendix A, available in the online supplemental material, it is clear that the value of  $\theta_M$  affects the upper bound ( $\mathcal{I}_{upper}$ ) of  $\mathcal{I}$ . When  $\theta_{min} < \theta_M < \frac{1}{2}$ , the value of  $\mathcal{I}_{upper}$  should be close to the lower bound of  $\mathcal{I}$ . In practice, we should set

$$\varepsilon \approx \frac{2m\theta_{min}^2}{1 - 2\theta_{min}}.$$
 (11)

For a given partition scheme, with a total of m partitions, identification of the partition with the minimum failure rate  $(\theta_{min})$  first requires calculation of the failure rates of each

partition, then identification of the minimum. Each partition's failure rate can be obtained in two ways:

- 1) It can be calculated directly as F/E (F is the number 448 of failures and E is the number of executed tests), if 449 the test history of the web service under test is 450 available.
- 2) It can be approximated by  $1/k_i$ , where  $k_i$  is the total 452 number of test cases executed before revealing a fault. 453

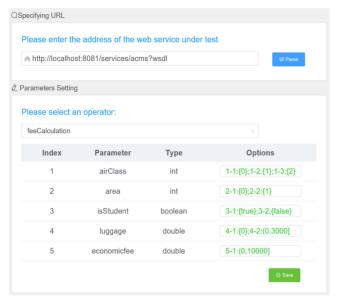

# 3.3 Prototype

This section describes a tool that partially automates DRT for 455 web services, called DRTester<sup>1</sup>. DRTester supports the following tasks in testing web services: a) WSDL parsing; b) partition 457 construction; c) setting DRT parameters (probability adjusting 458 factor  $\varepsilon$  and test profiles); and d) test case preparation and execution. The details of DRTester are as follows: 460

- 1) *Guidance*. This feature describes the steps the tester 461 should follow when testing a web service. 462
- 2) Configuration. This feature, as shown in Fig. 2, inter- 463 acts with the testers to obtain and set the information 464 related to testing the web service, including: the 465 address of the web service under test; the DRT 466 parameters and partition details; and the test case 467 preparation. The detailed steps are as follows: 468
  - Inputting and parsing the URL (Fig. 2a): We integrate 469 the WSDL parsing functionality provided by 470 MT4WS [24]. This enables all the (WSDL) parameters and their types to be automatically obtained. 472
  - Parameter setting (Fig. 2a): The tester is responsi- 473
     ble for selecting which operations of the current 474
     web service under test are to be tested, and for 475
     partitioning each parameter into disjoint choices. 476
  - *Partition setting (Fig. 2b)*: The tester is responsible 477 for specifying the partitions by combining the 478 choices associated with each parameter. 479
  - Test case generation (Fig. 2b): The tester is respon- 480 sible for specifying the mode of test case genera- 481 tion (either randomly generating test cases based 482 on the parameters, or uploading test cases gener- 483 ated using other techniques).
- 3) Execution. This feature presents a summary of the 485 testing results, including details of the test case exe-486 cution (input, expected output, partition, and result 487 (pass or fail)). For randomly generated tests, the tes-488 ter has to check each individual result. Otherwise, 489 when all tests have been completed, a report is gen-490 erated in a downloadable file.

The back-end logic is composed of several Restful APIs and 492 Java classes: The APIs are responsible for communicating 493 HTTP messages to and from the front-end interface. The controller class is responsible for updating the test profile according to the test results, and for selecting test cases from the 496 partitions. The selected test cases are wrapped in SOAP messages and sent to the web service under test through the proxy 498 class, which also intercepts the test results.

1. The prototype tool, together with a number of accompanying resources, has been made available at: https://githup.com/phantomDai/DRTester.git

510

511

512

We conducted a series of empirical studies to evaluate the performance of DRT.

#### **Research Questions**

In our experiments, we focused on addressing the following three research questions:

RQ1 How effective is DRT at detecting web service faults? Fault-detection effectiveness is a key criterion for evaluating the performance of a testing technique. This study used three popular real-life web services as subject programs, and applied mutation analysis to evaluate the effectiveness.

TABLE 1 Subject Web Services

Web service	LOC	Number of mutants
ACMS	116	3
CUBS	131	11
PBS	129	4

How do the number of partitions and the DRT 514 parameter  $\varepsilon$  impact on the failure detection effectiveness and efficiency of DRT? In our earlier work [14], we found that the DRT 517 parameter  $\varepsilon$  had a significant effect on DRT effi- 518 ciency, and that the optimal value of the parameter 519

could be related to the number of partitions. The 520 relationship between  $\varepsilon$  and the number of partitions 521 is examined through theoretical analysis, and veri- 522 523

fied through the empirical studies.

RO3 Compared with the baseline techniques, how efficient 525 is DRT at detecting web service faults in terms of time? 526 Compared with RT and PT, DRT incorporates the selec- 527 tion of partitions and test cases within a partition. Com- 528 pared with AT, which also introduces feedback and 529 adaptive control principles to software testing, DRT has 530 a simple but efficient control strategy. Thus, we are 531 interested in comparing the fault detection efficiency of 532 DRT, RT, PT, and AT in terms of their time costs.

# 4.2 Subject Web Services

Although a number of web services are publicly available, for 535 various reasons, their implementations are not. This renders 536 them unsuitable for our experiments, which involve the crea- 537 tion of faulty mutants (requiring access to the implementa- 538 tions). We therefore selected three web services as the subject 539 programs for our study, and implemented them ourselves, 540 based on real-life specification: Aviation Consignment 541 Management Service (ACMS); China Unicom billing 542 service (CUBS); and Parking billing service (PBS). 543 We used the tool MuJava [25] to conduct mutation analysis 544 [26], [27], generating a total of 1563 mutants. Each mutant was 545 created by applying a syntactic change (using one of all appli- 546 cable mutation operators provided by MuJava) to the original 547 program. Equivalent mutants, and those that were too easily 548 detected (requiring less than 20 randomly generated test 549 cases), were removed. To ensure the statistical reliability, we 550 obtained 50 different test suites using different random seeds, 551 then tested all mutants with all test suites, calculating the 552 average number of test cases needed to kill (detect) a mutant. 553 Table 1 summarizes the basic information of the used web 554 services and their mutants. A detailed description of each 555 web service is given in the following.

#### 4.2.1 Aviation Consignment Management Service (ACMS)

ACMS helps airline companies check the allowance (weight) 559 of free baggage, and the cost of additional baggage. Based 560

557

2. The implementations have been made available at: https:// github.com/phantomDai/subjects4tsc.git

TABLE 2

ACMS Baggage Allowance and Pricing Rules

		Domestic fligh	nts	International flights

Carry on (kg)	5	5	5	7	7	7			
Free checked-in (kg)	40	30	20	40	30	20/30			
Additional baggage pricing (kg)									

on the destination, flights are categorised as either domestic or international. For international flights, the baggage allowance is greater if the passenger is a student (30 kg), otherwise it is 20 kg. Each aircraft offers three cabin classes from which to choose (economy, business, and first), with passengers in different classes having different allowances. The detailed price rules are summarized in Table 2, where *price* means economy class fare and *weight* is the weight that exceeds the weight of the free carry.

## 4.2.2 China Unicom Billing Service (CUBS)

CUBS provides an interface through which customers can know how much they need to pay according to cell-phone plans, calls, and data usage. The details of several cell-phone plans are summarized in Tables 3, 4, and 5.

Consider a parking billing service that accepts the parking details for a vehicle, including the vehicle type, day of the week, discount coupon, and hours of parking. This service rounds up the parking duration to the next full hour, and then calculates the parking fee according to the hourly rates in Table 6. If a discount voucher is presented, a 50 percent discount off the parking fee is applied.

To facilitate better parking management, at the time of parking, customers may provide an estimation of parking duration, in terms of three different time ranges ((0.0,2.0], (2.0,4.0], and (4.0,24.0]). If the estimation and actual parked hours fall into the same time range, then the customer will receive a 40 percent discount; but if they are different ranges, then a 20 percent markup is applied. A customer may choose to either use a discount coupon, or provide an estimation of parking duration, but may not do both. No vehicles are allowed to remain parked for two consecutive days on a continuous basis.

#### 4.3 Variables

#### 4.3.1 Independent Variables

The independent variable is the testing technique. RT, RPT, DRT, and AT [12] were used for comparison.

#### 4.3.2 Dependent Variables

The dependent variable for RQ1 is the metric for evaluat- 600 ing the fault-detection effectiveness. Several effectiveness 601 metrics exist, including: the P-measure [28] (the probabil- 602 ity of at least one fault being detected by a test suite); the 603 E-measure [29] (the expected number of faults detected 604 by a test suite); the F-measure [30] (the expected number 605 of test case executions required to detect the first fault); 606 and the T-measure [31] (the expected number of test cases 607 required to detect all faults). Since the F- and T-measures 608 have been widely used for evaluating the fault-detection 609 efficiency and effectiveness of DRT-related testing techni- 610 ques [6], [8], [22], [23], [31], [32], they are also adopted in 611 this study. We use F and T to represent the F-measure 612 and the T-measure of a testing method. As shown in 613 Algorithm 1, the testing process may not terminate after 614 the detection of the first fault. Furthermore, because the 615 fault detection information can lead to different probabil- 616 ity profile adjustment mechanisms, it is also important to 617 see what would happen after revealing the first fault. 618 Therefore, we introduce the F2-measure [30] as the num- 619 ber of additional test cases required to reveal the second 620 fault after detection of the first fault. We use F2 to repre- 621 sent the F2-measure of a testing method, and  $SD_{measure}$  to 622 represent the standard deviation of metrics (where 623 measure can be F, F2, or T).

An obvious metric for RQ3 is the time required to detect 625 faults. Corresponding to the T-measure, in this study we 626 used *T-time*, the time required to detect all faults. *F-time* 627 and *F2-time* denote the time required to detect the first 628 fault, and the additional time needed to detect the second 629 fault (after detecting the first), respectively. For each of these 630 metrics, smaller values indicate a better performance. 631

In our study, we set the partitions by making use of a decision table (DT) [33]. A DT presents a large amount of complex decisions in a simple, straightforward manner, representing a set of decision rules under all exclusive conditional scenarios in a pre-defined problem. Typically, a DT consists of four parts:

- 1) The upper-left part lists the conditions denoted  $C_i$   $(i=1,\ldots,n)$ , where n is the number of conditions in the pre-defined problem, and  $n \ge 1$ ). Each condition  $C_i$  contains a set of possible options  $O_{i,q} \in CO_i = \{O_{i,1},\ldots,O_{i,t_i}\}$ , where  $t_i$  is the number of possible options for  $C_i$ , and  $q = \{1,\ldots,t_i\}$ .
- 2) The upper-right part shows the condition space, which is a Cartesian product of all the  $CO_i$  ( $SP(C) = CO_1 \times CO_2 \times ... \times CO_n$ ). Each element in the SP(C) is a condition entry (CE) with the ordered n-tuple.
- 3) The lower-left part shows all possible actions, represented  $A_j$  ( $j=1,\ldots,m$ , where m is the number of possible actions and  $m \ge 1$ ). Similar to  $CO_i$ , an action  $A_j$  contains a set of possible options  $O'_{i,p} \in AO_j =$

- $\{O_{j,1}',\ldots,O_{j,k_j}'\}$ , where  $k_j$  is the number of alternatives 653 for  $A_j$ , and  $p=\{1,\ldots,k_j\}$ .
- 4) The lower-right part shows the action space SP(A), 655 which is also a Cartesian product of all the  $AO_j$  656  $(SP(A) = AO_1 \times AO_2 \times ... \times AO_m)$ . Similar to CE, 657 each element in the SP(A) is an action entry (AE) 658 with the ordered m-tuple.

A DT *rule* is composed of a CE and its corresponding AE. 660 With DT, it is possible to obtain partition schemes with different granularities. For fine-grain partition schemes, each 662 CE of a DT *rule* corresponds to a partition; while for coarsegrained schemes, a partition corresponds to the union of a 664 group of partitions for which all CE of DT *rules* have the 665 same AE. The decision tables for ACMS, CUBS, and PBS are 666 shown in Tables 7, 8 and 9, respectively. In the tables,  $R_i$  667  $(i=1,2,\ldots,n)$  denotes the identified ith rule; n is the total 668 number of rules; and the checkmark ( $\checkmark$ ) under each rule indicates that the corresponding action should be taken. The 670 details of actions are provided in Table 10, where w is the 671 weight of baggage; price means economy class fare; op 672 means the monthly charge; call and data mean the call duration and data usage, respectively; freeCall and freeData 674

parking fall into the same time range; and 2: estimated 692 hours and the actual hours are in different time ranges).

As can be seen from the description above, because the DT 694 considers all parameters, and identifies their invalid combina-695 tions, it can provide a systematic and efficient way to partition 696 an input domain into disjoint subdomains, and then generate 697 test cases. In practice, each DT *rule* condition entry corre-698 sponds to a partition in which test cases cover some paths—699 thus, the faults in those paths have a chance of being detected. 700

#### 4.4.2 Initial Test Profile

Because test cases may be generated randomly during the test 702 process, a feasible method is to use a uniform probability distribution as the initial testing profile. On the other hand, testers may also use past experience to help guide selection of a 705 different probability distribution as the initial profile. In our 706 experiment, we used a uniform probability distribution for 707 the initial test profile. The initial test profiles of each web service are summarized in Table 11, where  $\langle s_i, p_i \rangle$  means 709 that the probability of selecting partition  $s_i$  is  $p_i$ .

#### 4.4.3 Constants

In the experiments, we were interested in exploring the relationship between the number of partitions and the DRT 713

TABLE 11
Initial Test Profile for Subject Web Services

Actual park	ing Hourly parking	Initial test					
hours	rates	profile					
ACMS	24 7	$ \begin{cases} \left\langle s_1, \frac{1}{24} \right\rangle, \left\langle s_2, \frac{1}{24} \right\rangle, \dots, \left\langle s_{24}, \frac{1}{24} \right\rangle \right\} \\ \left\langle s_1, \frac{1}{7} \right\rangle, \left\langle s_2, \frac{1}{7} \right\rangle, \dots, \left\langle s_7, \frac{1}{7} \right\rangle \end{cases} $					
CUBS	20 3	$ \begin{cases} \left\langle s_1, \frac{1}{20} \right\rangle, \left\langle s_2, \frac{1}{20} \right\rangle, \dots, \left\langle s_{20}, \frac{1}{20} \right\rangle \right\} \\ \left\langle \left\langle s_1, \frac{1}{3} \right\rangle, \left\langle s_2, \frac{1}{3} \right\rangle, \dots, \left\langle s_3, \frac{1}{3} \right\rangle \right\} \end{aligned} $					
PBS	18 3						

strategy parameter  $\varepsilon$ , and therefore selected a set of parameter values:  $\varepsilon \in \{1.0E\text{-}05, 5.0E\text{-}05, 1.0E\text{-}04, 5.0E\text{-}04, 1.0E\text{-}03, 5.0E\text{-}03, 1.0E\text{-}02, 5.0E\text{-}02, 1.0E\text{-}01, 2E\text{-}01, 3E\text{-}01, 4E\text{-}01, 5E\text{-}01\}.$  It should be noted that  $\varepsilon = 5E\text{-}01$  is already a large value. Consider the following scenario. For PBS, when the test is carried out under partition scheme 2, if  $\varepsilon = 7.5E\text{-}01$  and a uniform probability distribution is used as the testing profile (that is,  $p_i = 1/3$ ), then suppose that the first test case belonging to  $c_1$  is executed and does not reveal any faults, then, according to Formula (3), the value of  $p_1$  would become 0. It is important, therefore, that the initial value of  $\varepsilon$  should not be set too large.

# 4.5 Experimental Environment

Our experiments were conducted on a virtual machine running the Ubuntu 11.06 64-bit operating system, with two CPUs, and a memory of 2GB. The test scripts were written in Java. To ensure statistically reliable values [34] of the metrics (F-measure, F2-measure, T-measure, F-time, F2-time, and T-time), each testing session was repeated 30 times with 30 different seeds, and the average value calculated.

# 4.6 Threats To Validity

#### 4.6.1 Internal Validity

A threat to internal validity is related to the implementations of the testing techniques, which involved a moderate amount of programming work. However, our code was cross-checked by different individuals, and we are confident that all techniques were correctly implemented.

#### 4.6.2 External Validity

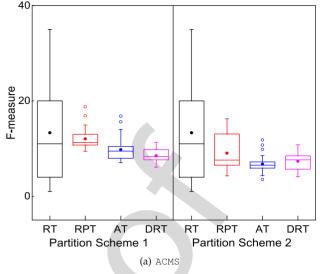

The possible threat to external validity is related to the subject programs and seeded faults under evaluation. Although the three subject web services are not very complex, they do implement real-life business scenarios of diverse application domains. Furthermore, 18 distinct faults were used to evaluate the performance. These faults cover different types of mutation operators and require an average of more than 20 randomly generated test cases to be detected. Although we have tried to improve the generalisability of the findings by applying different partitioning granularities, and 13 kinds of parameters, we anticipate that the evaluation results may vary slightly with different subject web services.

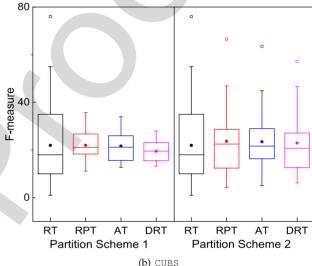

#### 4.6.3 Construct Validity

The metrics used in our study are simple in concept and straightforward to apply, and hence there should be little threat to the construct validity.

#### 4.6.4 Conclusion Validity

As reported for empirical studies in the field of software engineering [34], at least 30 observations are necessary to ensure the statistical significance of results. Accordingly, we have run a sufficient number of trials to ensure the reliability of our experimental results. Furthermore, as will be discussed in Section 5, we also conducted statistical tests to confirm the significance of the results.

and each solid circle represents the mean value of the metric.

It can be observed from the figures that, in an overwhelming majority of cases, DRT was the best performer in terms of F-, F2-, and T-measure, followed by AT, RPT, and RT. On the other hand, RT may be the best performer occasionally or the worst performer in terms of F-, F2-, and T-measure, which means that the fault detection effectiveness of RT is not stable. In contrast, DRT and AT show a relatively stable fault detection effectiveness. We also conducted statistical testing to verify the significance of this observation, using the Holm-Bonferroni method [30] (with p-value equal to 0.05) to determine which pairs of testing techniques had significant differences. The statistical data are shown in Table 12, where each cell gives the number of scenarios where the technique above (in the table) performed better than one to the left. For example, the "6" in the top right cell of Table 12 indicates that, of 6 scenarios (two partition schemes × three web services), DRT had lower T-measure scores than RT for 6, with the faultdetection capabilities of these two techniques being significantly different.

Table 12 clearly shows that the differences between pairs of testing techniques are all significant.

# 5.2 RQ2: Relationship between Partition Number and $\varepsilon$

In Section 3.2, we analyzed the relationship between the number of partitions and the DRT parameter  $\varepsilon$ . In this section, we show that our theoretical analysis provides useful guidance to testers to set the value of  $\varepsilon$ .

We used three web services to validate our theoretical analysis. Before starting the test, it is necessary to know the failure rate  $\theta_i$  of partition  $s_i$ . From Tables 2, 3, 4 and 5, it can be observed that the values of some parameters (such as the baggage weight, the call duration, and parking duration) are such that the total number of test case values in a partition could be infinite. For such a situation, we approximate the failure rate  $\theta_i$  of  $s_i$  by  $1/k_i$  (where  $k_i$  is the total number of test cases executed before revealing a fault). According to Formula (19), the theoretically optimal values of  $\varepsilon$  in each scenario for each web service are shown in Table 13, where  $\varepsilon^*$  denotes the theoretical value of  $\varepsilon$ . We ran a series of experiments with the parameters set according to those in Table 13: The F-, F2-, and T-measure results for each program are shown in Fig. 6, where  $\varepsilon_1^*$  and  $\varepsilon_2^*$ denote the theoretical values of parameter  $\varepsilon$  in the two different partition schemes, respectively. For ease of presentation and understanding, we used  $log_{100}(1.0E05 \times \varepsilon)$  for the

TABLE 13
Theoretical Optimal Values of DRT Parameter

	2	1.492E-3	1.340E-5

horizontal axis in Fig. 6. Apart from the DRT strategy parameter  $\varepsilon$ , all other experimental settings remained the same as in 885 Section 5.1.

From Fig. 6, we have the following observations:

- In most scenarios, the DRT strategy with theoretis88 cally optimum parameter value performs best. Furthermore, the DRT strategy performs better when 890
  the parameter values are near the theoretically optimum value than when not.

  892
- From Fig. 6a, it can be observed that the DRT strategy 893 with larger parameter values performs better than 894 with the theoretically optimum value, in terms of the 895 F-measure. The main reason for this is that, for this 896 scenario, the maximum failure rate ( $\theta_M = 4.781E 3$ ) 897 is large and the number of partitions is small: When 898 the parameter value is large, the probability of selecting partitions with lower failure rates is quickly 900 reduced, and the probability of selecting partitions 901 with larger failure rates is quickly increased, according 902 to Formulas (3) and (4).

#### 5.3 RQ3: Fault Detection Efficiency

The F-, F2-, and T-time results for ACMS, CUBS, and PBS are 905 summarized in Table 14, where the values of DRT parame-906 ters for the subject web services are the same as those in 907 Section 5.1. The F-, F2-, and T-time results of DRT with dif-908 ferent parameter values are summarized in Appendix B, 909 available in the online supplemental material. It can be 910 observed from the table that, in general, DRT had the best 911 performance; RPT marginally outperforms RT; and AT had 912 the worst performance.

As was done for the F-, F2-, and T-measure data, we used 914 the Holm-Bonferroni method to check the difference between 915 each pair of testing strategies in terms of F-time, F2-time, and 916 T-time, as shown in Table 15. Table 15 shows that: a) DRT was 917 significantly better than AT in terms of F-/F2-/T-time; b) DRT 918 was significantly better than RT and RPT in terms of 919 F2-/T-time; and c) DRT marginally outperformed RT and 920 RPT in terms of F-time. In other words, the additional computation incurred in DRT by updating the test profile is compensated for in terms of test execution savings.

In summary, the DRT strategy is considered the best testing 924 technique across this three metrics, RPT marginally outper-925 formed RT, and DRT, RPT, and RT significantly outperformed 926 AT. 927

938

939

940

941

942

943

944

Based on the evaluation, we have the following observations:

- DRT outperformed RT, RPT, and AT, according to all the applied metrics for all three studied web services. DRT marginally outperformed AT in terms of the F-, F2-, and T-measure, for all the studied web services. Moreover, AT incurs heavier computational overhead, and takes a significantly longer time. For instance, AT required 32429.07ms to select and execute sufficient test cases to detect all faults in CUBS, while DRT only needed 30.21ms (Table 14). This indicates that among RT, RPT, and AT, DRT should be chosen.
- DRT is more effective in terms of the F-, F2-, and T-measure when the parameter settings are optimal (according to the theoretical analysis): In most cases, DRT has the best performance for all three web services, according to these three metrics (F-measure,

F2-measure, and T-measure) when following the 945 guidelines for the parameter settings. This highlights 946 the usefulness of the parameter-setting guidelines. 947

948

956

We also note the following limitations:

- While DRT outperformed RT and RPT in terms of 949 fault detection effectiveness and efficiency, this was 950 achieved at the cost of the additional effort required 951 to set the partitions and test profiles.
- Applying DRT involves setting parameters, which 953
  may not be trivial. Even when following the theoretical 954
  guidelines.

# 6.1 Testing Techniques for Web Services

In recent years, a lot of effort has been made to test web services [4], [13], [35], [36]. Test case generation or selection is core to testing web services, and model-based [37] and specification-based [38] techniques are two common approaches. Before making services available on the Internet, testers can use model-based techniques to verify whether or not the behavior of the WSUT meets their requirements. In these techniques, test data can be generated from a data model that specifies the inputs to the software—this data model can be built before, or in parallel to, the software development process. Verification methods using technologies such as theorem-proving [39], models [40] and Petri-Nets [41] also exist.

All of the above approaches aim to generate test cases without considering the impact of test case execution order on test efficiency. In contrast, Bertolino et al. [42] proposed using the category-partition method [43] with XML schemas to perform XML-based partition testing. Because PT aims to find subsets of all possible test cases to adequately test a system, it can help reduce the required number of test cases. Our approach involves software cybernetics and PT: In DRT, selection of a partition is done according to the testing profile, which is updated throughout the testing process. An advantage of DRT is that partitions with larger failure rates have higher probabilities of selection. Zhu and Zhang [44] proposed a collaborative testing framework, where test tasks are completed using collaborating test services—a test service is a service assigned to perform a specific testing task. Our framework (Section 3.1) aims to find more faults in the WSUT, with the result of the current test case execution providing feedback to the control system so that the next test case selected has a greater chance to reveal faults.

Most web service testing techniques assume that the computed output for any test case is verifiable, which is, however, not always true in practice (a situation known as the oracle problem [19]). Thus, many testing techniques may not be applicable in some cases. To address the oracle problem for

TABLE 15

Number of Scenarios Where the Technique on the Top Row has a Lower Metric (F-/F2-/T-Time)

Score Than the Technique on the Left Column

	F-time				F2-time				T-time			
	RT	RPT	AT	DRT	RT	RPT	AT	DRT	RT	RPT	AT	DRT

ΑT	6	5	_	6	6	6	_	6	6	6	_	6
DRT	2	2	0	_	0	1	0	_	0	0	0	_

testing web services, Sun *et al.* [21] proposed a metamorphic 996 testing [45], [46] approach that not only alleviates the oracle 997 problem, but is also a practical and efficient option for testing 998 web services. They conducted a case study that showed that 999 up to 94.1 percent of seeded faults could be detected without 1000 the need for oracles.

#### 6.2 Improving RT and PT

Based on the observation that failure-causing inputs tend to 1003 cluster into contiguous regions in the input domain [10], [11], 1004 much work has been done to improve RT [6], [7], [9]. Adaptive 1005 random testing [7], [9] is a family of techniques based on random testing that aim to improve the failure-detection effectiveness by evenly spreading test cases throughout the input 1008 domain. One well-known ART approach, FSCS-ART, selects a 1009 next test input from the fixed-size candidate set of tests that is 1010 farthest from all previously executed tests [47]. Many other 1011 ART algorithms have also been proposed, including RRT [48], 1012 DF-FSCS [49], and ARTsum [50], with their effectiveness examined and validated through simulations and experiments.

Adaptive testing (AT) [8], [51], [52] takes advantage of 1015 feedback information to control the execution process, and 1016 has been shown to outperform RT and RPT in terms of the 1017 T-measure and the number of detected faults, which means 1018 that AT has higher efficiency and effectiveness than RT and 1019 RPT. However, AT may require a rather long execution 1020 time in practice. To alleviate this, Cai *et al.* [6] proposed 1021 DRT, which uses testing information to dynamically adjust 1022 the testing profile. There are several things that can impact 1023 on DRT's test efficiency. Yang *et al.* [32] proposed A-DRT, 1024 which adjusts parameters during the testing process.

#### 7 CONCLUSION

In this paper, to address the challenges of testing SOA-based 1027 applications, we have presented a dynamic random testing 1028 (DRT) method for web services. Our method uses random 1029 testing to generate test cases, and selects test cases from different partitions in accordance with a testing profile that is 1031 dynamically updated in response to the test data collected. In 1032 this way, the proposed method enjoys benefits from both random testing and partition testing.

We proposed a framework that examines key issues when 1035 applying DRT to test web services, and developed a prototype 1036 to make the method practical and effective. To guide testers to 1037 correctly set the DRT parameters, we used a theoretical analy- 1038 sis to study the relationships between the number of partitions 1039 (m) and the probability adjusting factor  $(\varepsilon)$ . Three real web 1040 services were used as experimental subjects to validate the 1041

1167

feasibility and effectiveness of our approach. Our experimental results show that, in general, DRT has better performance than both RT and RPT, in terms of the F-, F2-, and T-measures, and always outperforms when the  $\varepsilon$  settings follow our guidelines. In other words, our theoretical analysis can provide genuinely useful guidance to use DRT.

In our future work, we plan to conduct experiments on more web services to further validate the effectiveness, and identify the limitations of our method.

Chang-Ai Sun received the bachelor degree in computer science from the University of Science and Technology Beijing, China, and the PhD degree in computer science from Beihang University, China. He is currently a professor with the School of Computer and Communication Engineering, University of Science and Technology Beijing. Before that, he was an assistant professor at Beijing Jiaotong University, China, a postdoctoral fellow at the Swinburne University of Technology, Australia, and a postdoctoral fellow

at the University of Groningen, The Netherlands. His research interests include software testing, program analysis, and service-oriented computing. He is a senior member of the IEÉE.

Hepeng Dai received the bachelor's degree in information and computing sciences from the China University of Mining and Technology, Beijing, and the master's degree in software engineering from the University of Science and Technology Beijing, China. He is currently working toward the PhD degree in the School of Computer and Communication Engineering, University of Science and Technology Beijing, China. His current research interests include software testing and debugging.

Guan Wang received the bachelor's degree in 1239 computer science from the University of Science 1240 and Technology Beijing. He is currently working toward the master's degree at the School of Com- 1242 puter and Communication Engineering, University 1243 of Science and Technology Beijing. His current 1244 research interests include software testing and 1245 service-oriented computing. 1246

Dave Towey received the BA and MA degrees 1247 from the University of Dublin, Trinity College, 1248 Dublin, Ireland, PgCertTESOL degree from the 1249 Open University of Hong Kong, Hong Kong, the 1250 MEd degree from the University of Bristol, Bristol, 1251 United Kingdom, and the PhD degree from the Uni- 1252 versity of Hong Kong, Hong Kong. He is currently 1253 an associate professor with the School of Com- 1254 puter Science, University of Nottingham Ningbo 1255 China. His current research interests include tech- 1256 nology-enhanced teaching and learning, and soft-

ware testing, especially metamorphic testing and adaptive random testing. 1258 He is a member of both the IEEE and the ACM. 1259

Tsong Yueh Chen received the BSc and MPhil 1260 degrees from the University of Hong Kong, 1261 Hong Kong, the MSc and DIC degrees from the 1262 Imperial College of Science and Technology, 1263 London, United Kingdom, and the PhD degree in 1264 computer science from the University of Mel- 1265 bourne, Parkville, Australia. He is currently a pro- 1266 fessor of software engineering at the Department 1267 of Computer Science and Software Engineering, 1268 Swinburne University of Technology. He is the inventor of metamorphic testing and adaptive ran- 1270 dom testing. He is a member of the IEEE.

Kai-Yuan Cai received the BS, MS, and PhD 1272 degrees from Beihang University, Beijing, China, 1273 in 1984, 1987, and 1991, respectively. He has 1274 been a full professor at Beihang University since 1275 1995. He is currently a Cheung Kong scholar 1276 (chair professor) appointed by the Ministry of Edu- 1277 cation of China in 1999. His main research inter- 1278 ests include software testing, software reliability. 1279 reliable flight control, and software cybernetics.
